1 Introduction to the hypothetical bartering system

You have \$10, and a beer is 2\$. Very quickly you can see that if you spend all 10\$, you will get 5 beers. Once you've drunken the 5 beers, you are left with 5 beer bottles and 5 caps. The store owner strikes you a deal. If you give him two empty bottles or four bottle caps, he'll give you a new bottle of beer. He is also kind enough to let you drink before you pay. How many drinks you can get?

2 Modeling amount of caps and bottles

2.1 Vector representation of caps and bottles

$$\begin{bmatrix} a \\ b \end{bmatrix}$$

Will be the vector that represents the bottles and caps such that a is the amount of bottles, and b is the amount of caps.

2.2 Representation of the bartering system

If we can spend two empty bottles and receive a full drink, that is equivalent to spending two bottles and getting one bottle and one cap. We will represent this operation as the addition of the following vector;

$$\begin{bmatrix} -2 + 1 \\ 1 \end{bmatrix}$$

And since we can drink before we pay, having only one empty bottle is enough to drink.

$$\begin{bmatrix} -1 \\ 1 \end{bmatrix}$$

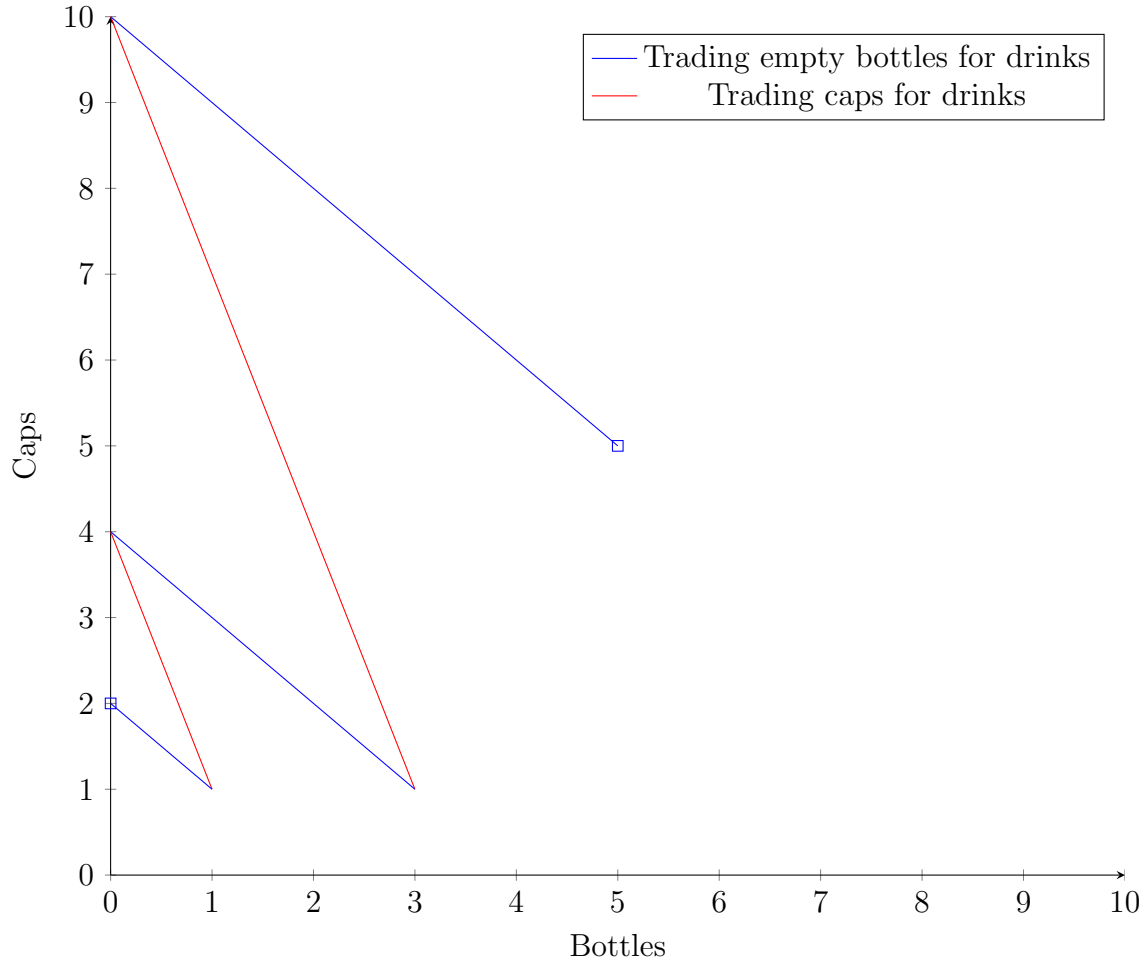

Using 4 caps can be represented similarly

$$\begin{bmatrix} 1 \\ -4 + 1 \end{bmatrix}$$

Which can simply be evaluated to.

$$\begin{bmatrix} 1 \\ -3 \end{bmatrix}$$

These two operations can be represented geometrically as a translation of a point on a 2 dimensional Cartesian plane. For example, if we start with 5 empty bottles and 5 empty caps, we can trace the motion of the point as following.

3 Analysis of the graph

We know from the context of the problem, that the final state can only be the following points:

$$(0, 0)$$

$$(0, 1)$$

$$(0, 2)$$

Because having either 1 bottle, or 3 caps is enough to do another transaction.

Visually, you can already tell that it's impossible to get to the point $(0, 0)$ unless if you have already started there (sorry mate, you gotta buy some beer to play the game).

You can also tell that you cannot get to $(0, 1)$, because that means you came from $(1, 0)$ through a blue line, but that means you came from $(0, 2)$ from a red line, which is impossible because $(0, 2)$ is not enough to continue a transaction.

So already from this graph, you can tell that you will always end up with 2 caps left over (if we ignore the trivial case that you do not buy beer in the first place).

3.1 Algebraic Solution

Let \vec{i} be the initial state, \vec{f} be the final state, c be the cap-based transactions, and b be the bottle-based transaction.

$$\begin{aligned}\vec{i} + c \begin{bmatrix} -3 \\ 1 \end{bmatrix} + b \begin{bmatrix} 1 \\ -1 \end{bmatrix} &= \vec{f} \\ c \begin{bmatrix} -3 \\ 1 \end{bmatrix} + b \begin{bmatrix} 1 \\ -1 \end{bmatrix} &= \vec{f} - \vec{i} \\ \begin{bmatrix} -3 & 1 \\ 1 & -1 \end{bmatrix} \begin{bmatrix} c \\ b \end{bmatrix} &= \vec{f} - \vec{i} \\ \begin{bmatrix} c \\ b \end{bmatrix} &= \frac{1}{2} \begin{bmatrix} -1 & -1 \\ -1 & -3 \end{bmatrix} (\vec{f} - \vec{i})\end{aligned}$$

The goal is to get as drunk as possible, which is reaching as many transactions as possible, thus we want to maximize $b+c$ with respect to the elements of f . The above matrix equation can be represented as the following set of equations.

$$\begin{aligned}c &= \frac{1}{2}(-(f_c - i_c) - (f_b - i_b)) \\ b &= \frac{1}{2}(-(f_c - i_c) - 3(f_b - i_b)) \\ c + b &= \frac{1}{2}(-2(f_c - i_c) - 4(f_b - i_b))\end{aligned}$$

Which can be simplified to:

$$\begin{aligned}c &= \frac{1}{2}(-f_c - f_b + i_c + i_b) \\ b &= \frac{1}{2}(-f_c - 3f_b + i_c + i_b) \\ c + b &= (-f_c - 2f_b + i_c + 2i_b)\end{aligned}$$

Using the typical optimization with derivatives isn't going to help us here, because the function is linear with respect to both f_c and f_b . Instead we can use the constraint that c , b , and $c + b$ must be natural numbers (in my definition, the natural numbers include 0).

$$\begin{aligned}c &\in \mathbb{N} \\ -f_c - f_b + i_b + i_c &\in 2\mathbb{N}\end{aligned}$$

Since $i_b = i_c$, $i_b + i_c \in 2\mathbb{N}$

$$\begin{aligned}-f_c - f_b &\in 2\mathbb{Z} \\ f_c + f_b &\in 2\mathbb{N}\end{aligned}$$

Thus, we can say that f_c and f_b have the same parity.

4 Using the final state of the vector to deduce the amount of drinks drunk

Since two empty bottles can get you a drink and a drink is worth \$2, then that means one bottle is worth \$1. Similarly since four bottle caps can get you a drink and a drink is worth \$2, then that means bottle cap is worth \$0.5.

Since a full drink is consisted of one cap, one bottle, and some drink, we can use simple algebra to deduce that:

$$\$2 = d + \$1 + \$0.5 \tag{1}$$

$$d = \$0.5 \tag{2}$$

the worth of the drink is \$0.5. If we started with \$10 dollars, and we are left with a bottles and b caps, then:

$$\$10 = \$0.5x + \$a + \$0.5b \tag{3}$$

$$x = \frac{\$10 - \$a - \$0.5b}{\$0.5} \tag{4}$$
